Caramelization

Carametization is one of the most important types of browning processes in foods, together with Malifard reactions and enzymatic browning. Carmetization leads desirable colour and flavour in bakery's goods, coffee, beverages, beer and peanuts. Undesirable effects of caramelization are for example burned sugar smell and blackening.

Caramelization causes important changes in foods, not only in colour but also in flavour. As no enzymes are involved in the carmelization process, it is a non-enzymatic browning reaction.

Caramelization occurs during dry heating and reasting of foods with a high concentration of carbohydrates (sugars).

Simply speaking, caramelization is the process of removal of water from a sugar (such as sucrose or glucose) followed by isomerization and polymerisation steps. In reality the caramelization process is a complex series of chemical reactions, which is still poorty understood.

The process of caramelization starts with the melting of the sugar at high temperatures, followed by foaming (boiling). At this stage saccharose (sugar) decomposes into glucose and fructose. This is followed by a condensation step, in which the individual sugars lose water and react with each other to for example difructose-anhydride. The next step is the isomerization of aldoses to ketoses and further dehydration reactions. The last series of reactions include both fragmentation reactions (flavour production) and polymerization reactions (colour production).

Caramelization starts at relatively high temperatures as compared to the other browning reactions, and depends on the type of sugar. Table 1 below shows the initial carameteration temperatures of some common carbohydrates. This table is based on pure carbohydrates, in foods often several different carbohydrates and other components are present; all these may influence the caramelization temperature as well as the different steps and reactions, and thus the final flavours and colours that are produced.

Table 1: Initial caramelization temperatures of common carbohydrates

Sugar	Lemberatrice	
Fruciose	110° ¢	
Galactose	160° C	*
Glucose	160° C	
Maltose	180° C	
Seccharose	160° C	

The highest rate of the colour development is caused by fructose as caramelization of fructose starts at lower temperature. Baked goods made from honey or fructose syrup thus are generally a bit darker than those made with sugar.

During caramelization several flavour components as well as polymeric caramels are produced. Caramels are complex mixture of various high molecular weight components. They can be classified into three groups:

- Carametans (C₃₄H₃₆O₁₆)
- Cárámelens (C₃₆H₆₀O₂₆)
- Caramelins (C₁₂₅H₁₈₈O₅₀)

These polymers are often used as colours in commercial food products, from colas to say sauce, confectionary and ice-cream. They are labelled as £150.

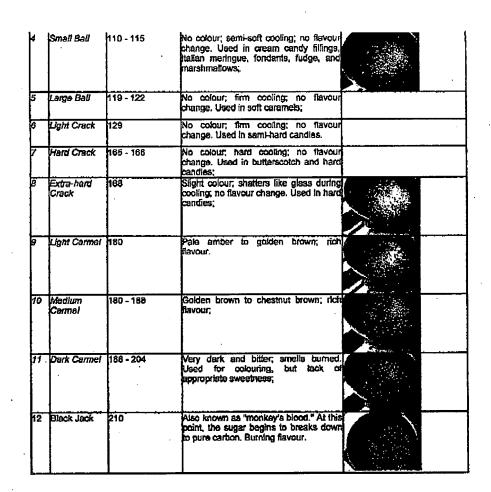

Commercial caramets are produced directly by heating sugar, or by heating sugar in the presence of co-factors, such as ammonia or sulphite. This results in caramets with different colours or charged caramets. These espects are very important for the use of different caramels in foods. Caramels used to colour soft drinks should be negatively charged to prevent reaction with phosphates which causes precipitation and loss of colour. On the other hand, caramels used for bakery goods should be positively charged.

The different stages of caramel production all have distinct names, based on the characteristics of the product, see table 2 below. Thread indicates the fact that sugar can be spun into soft or hard threads, ball indicates that sugar easily can be moulded into a proper shape, crack indicates that the suger will hard after cooling (and cracks when it is broken). Only when colour appears the names refer to caramel.

Table 2 : Stage of caramelization of saccharose (table sugar)

Ste	Ď	Temperature °C	Description and use	image
1	Evaporation of water	100	Sugar is melted and impurities rise to the surface;	0
2	Small Thread	102	No colour; soft cooling; no flavou change. Used in frostings.	
3	Large Thread	104	No colour, soft cooling; no flavou change. Used in preserves.	ar.

Food-Info.net: Caramelization

Caramelization reactions also result in the formation of flavours. Discetyl is an important flavour compound, produced during the first stages of carametration. Diacetyl is mainly responsible for a buttery or butterscotch flavour. Diacetyl is not only produced by carametration, it can also be produced by bacteria in fermented products, such as beer and yoghurt.

Besides discetyl hundrede of other flavour compounds are produced for Instance furans like hydroxymethyffurfurel (HMF) and hydroxyacetylfuran (HAF), furanones such as hydroxydimethylfuranone (HDF), dihydroxydimethylfuranone (DDF) end meltol from disaocharides and hydroxymaltol from monosaccharides.

Hydroxymethylfurfural (HMF) is found in honey, juices, milk but also in organities. Hydroxyacetylfuran (HAF) has a sweet arome and a low odour threshold. Mattol has a taste reminiscent of freshly beked bread and is used as a flavour enhancer (E636) in breads and cakes.
